

Ballistic Phase of Self-Interacting Random Walks

Dmitry Ioffe and Yvan Velenik

Technion and Université de Genève

April 3, 2008

Abstract

We explain a unified approach to a study of ballistic phase for a large family of self-interacting random walks with a drift and self-interacting polymers with an external stretching force. The approach is based on a recent version of the Ornstein-Zernike theory developed in [Campanino et al. \(2003, 2004, 2007\)](#). It leads to local limit results for various observables (e.g., displacement of the end-point or number of hits of a fixed finite pattern) on paths of n -step walks (polymers) on all possible deviation scales from CLT to LD. The class of models, which display ballistic phase in the “universality class” discussed in the paper, includes self-avoiding walks, Domb-Joyce model, random walks in an annealed random potential, reinforced polymers and weakly reinforced random walks.

1 Introduction and results

Self-interacting polymers and random walks have received much attention by both physicists and probabilists. As the resulting models are non-markovian, their analysis requires new techniques, and many basic questions remain open.

[Chayes \(2007\)](#) recently pointed out that the presence of an arbitrary non-zero drift turns a Self-Avoiding Walk on \mathbb{Z}^d into a “massive” model, and used this observation to prove the existence of a positive speed, using renewal techniques of Ornstein-Zernike-type, in the spirit of ([Chayes and Chayes, 1986](#)). A similar approach was used by [Flury \(2007a\)](#) in order to study non-directed polymers in a quenched random environment, under the influence of a drift: after suitable reduction to an annealed setting (at the cost of considering two interacting copies of the polymer), he used the same Ornstein-Zernike approach in order to prove equality of quenched and annealed free energies. Notice that introducing a drift in such polymer models is very reasonable from the point of view of Physics, as it is equivalent to pulling the polymer with a constant force at one endpoint, the other being pinned.

Ornstein-Zernike renewal techniques have known considerable progress in recent years, allowing nonperturbative control of percolation connectivities ([Campanino and Ioffe, 2002](#)), Ising correlation functions ([Campanino et al., 2003, 2004](#)) and more generally connectivities in random cluster models ([Campanino et al., 2007](#)), in the whole subcritical regime.

The purpose of this note is to point out that the approach of ([Campanino et al., 2003, 2004, 2007](#)) allows a unified and a detailed treatment of self-interacting polymers or self-

interacting walks in ballistic regime. In particular, we shall explain how to use it in order to prove that,

- For self-interacting polymers with a repulsive interaction (see below), a positive drift gives rise to a ballistic phase, in a very strong sense (local limit theorem for the endpoint).
- For self-interacting polymers with an attractive interaction (see below), there is a sharp transition between a confined phase and a ballistic phase as the drift increases; in the latter regime, we establish again a local limit theorem for the endpoint.
- These behaviours are stable under small perturbations (in a sense defined below). In addition to allowing us to consider mixed attractive/repulsive models, this also makes it possible to prove local limit theorems for some models of reinforced random walk with drift, strengthening the recent results obtained by [van der Hofstad and Holmes \(2007\)](#) using the lace expansion.
- In all cases mentioned, the local limit theorem can be readily complemented by a functional CLT for the ballistic path.
- In the ballistic phase, these results can be complemented by sharp local limit theorems for general local observables of the path. This permits for example a strong version of Kesten's pattern Theorem ([Kesten, 1963](#)) in this regime.

We would also like to remark that the approach could be pushed to analyse the interaction of paths as, e.g., considered in ([Flury, 2007a](#)), in order to analyse random polymers in quenched environment.

For the sake of readability, we make some simplifying assumptions in the sequel (for example, on the nearest neighbour nature of paths or on the form of the local observables), but the technique is flexible enough to be applicable in numerous other situations.

1.1 Class of models

For each nearest neighbour path $\gamma = (\gamma(0), \dots, \gamma(n))$ on \mathbb{Z}^d define:

- Length $|\gamma| = n$ and displacement $D(\gamma) = \gamma(n) - \gamma(0)$.
- Local times: For a given a site $x \in \mathbb{Z}^d$ set

$$l_x(\gamma) = \sum_{k=0}^{|\gamma|} \mathbb{1}_{\{\gamma(k)=x\}}.$$

Similarly, one defines local times $l_b(\gamma)$ for either un-oriented or oriented nearest neighbour bonds b .

- Potential $\Phi(\gamma)$: In this paper we shall concentrate on potentials Φ which depend only on bond or edge local times of γ . That is,

$$\Phi(\gamma) = \sum_{x \in \mathbb{Z}^d} \phi(l_x(\gamma)) \quad \text{or} \quad \Phi(\gamma) = \sum_b \phi(l_b(\gamma)). \quad (1.1)$$

To every $h \in \mathbb{R}^d$ and $\lambda \in \mathbb{R}$, we associate grand-canonical weights defined by

$$W_{h,\lambda}(\gamma) = e^{-\Phi(\gamma) + (h, D(\gamma)) - \lambda|\gamma|}, \quad (1.2)$$

where (\cdot, \cdot) is the usual scalar product on \mathbb{R}^d . If h or λ equal to zero, then the corresponding entry is dropped from the notation.

The important assumptions are those imposed on the potential Φ in (1.1). In all the models we are going to consider,

(N) $\phi(0) = 0$ and ϕ is a non-negative and non-decreasing function on \mathbb{N} .

Furthermore, we shall distinguish between the repulsive case,

(R) For all $l, m \in \mathbb{N}$, $\phi(l + m) \geq \phi(l) + \phi(m)$;

and the attractive case,

(A) For all $l, m \in \mathbb{N}$, $\phi(l + m) \leq \phi(l) + \phi(m)$.

In the attractive setup, there is no loss of generality in restricting our attention to sublinear potentials,

(SL) $\lim_{n \rightarrow \infty} \phi(n)/n = 0$.

Finally, we shall consider small perturbations of the above two pure (attractive or repulsive) cases.

Whichever model we are going to consider, the main object of our study is the canonical path measure,

$$\mathbb{P}_n^h(\cdot) = \frac{W_h(\cdot)}{Z_n^h},$$

where,

$$Z_n^h = \sum_{\gamma(0)=0, |\gamma|=n} W_h(\gamma).$$

Note that in the attractive case condition **(SL)** simply boils down to a choice of normalization for the partition functions Z_n^h .

1.2 Collection of examples

Two main examples of repulsive interactions are

1. Site or bond self-avoiding walks with $\phi(l) = \infty \cdot \delta\{l > 1\}$.
2. Domb-Joyce model with $\phi(l) = \beta l(l - 1)/2$.

Two examples of attractive interactions are

1. Annealed random walks in random potential,

$$\phi(l) = -\log \mathbb{E} e^{lV},$$

where V is a *non-positive* random variable.

2. Edge or site reinforced polymers with

$$\phi(l) = \sum_1^l \beta_k,$$

where $\{\beta_k\}$ is a *non-negative* and *non-increasing* sequence.

1.3 Connectivity constants, Lyapunov exponents and Wulff shapes

The connectivity constant

$$\lambda_0 \triangleq \lim_{n \rightarrow \infty} \frac{\log Z_n}{n}$$

is well defined and finite in both repulsive and attractive cases. Indeed, since ϕ is non-negative and non-decreasing,

$$e^{-\phi(1)n} \leq Z_n \leq (2d)^n.$$

On the other hand, $Z_{n+m} \leq Z_n Z_m$ in the case of repulsion, whereas $Z_{n+m} \geq Z_n Z_m$ in the attractive case.

As we shall check in the Appendix it is always the situation in the attractive case (under the normalisation **(SL)**) that,

$$\lambda_0 = \log(2d). \tag{1.3}$$

There are two slightly different approaches to Lyapunov exponents which we are going to employ: For every $x \in \mathbb{Z}^d$, let \mathcal{D}_x be the family of nearest neighbour paths from 0 to x . The family \mathcal{H}_x comprises those paths from \mathcal{D}_x which hit x for the first time. Formally,

$$\mathcal{H}_x = \{\gamma \in \mathcal{D}_x : l_x(\gamma) = 1\}.$$

Define

$$\mathbb{D}_\lambda(x) = \sum_{\gamma \in \mathcal{D}_x} W_\lambda(\gamma) \quad \text{and} \quad \mathbb{H}_\lambda(x) = \sum_{\gamma \in \mathcal{H}_x} W_\lambda(\gamma), \tag{1.4}$$

where, as before, $W_\lambda(\gamma) = e^{-\Phi(\gamma) - \lambda|\gamma|}$. Notice that

$$\mathbb{H}_\lambda(x) \leq \mathbb{D}_\lambda(x) \leq \sum_{n \geq \|x\|_1} Z_n e^{-\lambda n}, \tag{1.5}$$

which is converging for every $\lambda > \lambda_0$.

For $\lambda > \lambda_0$ define now

$$\xi_\lambda(x) = - \lim_{M \rightarrow \infty} \frac{1}{M} \log \mathbb{H}_\lambda(\lfloor Mx \rfloor) = - \lim_{M \rightarrow \infty} \frac{1}{M} \log \mathbb{D}_\lambda(\lfloor Mx \rfloor). \tag{1.6}$$

As we shall recall in the Appendix,

Proposition 1.1. *For every $\lambda > \lambda_0$ the function ξ_λ in (1.6) is well-defined. Furthermore, ξ_λ is an equivalent norm on \mathbb{R}^d , and*

$$\max_{x \in \mathbb{S}^{d-1}} \xi_\lambda(x) \leq c(d) \min_{x \in \mathbb{S}^{d-1}} \xi_\lambda(x). \tag{1.7}$$

Finally, $\xi_{\lambda_0} \triangleq \lim_{\lambda \downarrow \lambda_0} \xi_\lambda$ is identically zero in the repulsive case **(R)**, whereas it is strictly positive in the attractive case **(A)+(SL)**.

For every $\lambda \geq \lambda_0$ define the Wulff shape,

$$\mathbf{K}_\lambda = \left\{ h \in \mathbb{R}^d : (h, x) \leq \xi_\lambda(x) \ \forall x \in \mathbb{R}^d \right\}. \quad (1.8)$$

The name Wulff shape is inherited from continuum mechanics, where \mathbf{K}_λ is the equilibrium crystal shape once ξ_λ is interpreted to be a surface tension. Alternatively, one can describe \mathbf{K}_λ in terms of polar norms, as was done, e.g., in (Flury, 2007b): introducing the polar norm

$$\xi_\lambda^*(h) = \max_{x \neq 0} \frac{(h, x)}{\xi_\lambda(x)} = \max_{\xi_\lambda(x)=1} (h, x).$$

we see that \mathbf{K}_λ can be identified with the corresponding unit ball,

$$\mathbf{K}_\lambda = \{h : \xi_\lambda^*(h) \leq 1\}.$$

This way or another, in view of Proposition 1.1, the limiting shape \mathbf{K}_{λ_0} has non-empty interior in the attractive case, whereas $\mathbf{K}_{\lambda_0} = \{0\}$ in the repulsive case.

1.4 Main result

Let $h \in \mathbb{R}^d \setminus \{0\}$. Assume that the potential Φ in (1.1) satisfies condition **(N)**. In all the cases under consideration the displacement per step $D(\gamma)/n$ satisfies under \mathbb{P}_n^h a large deviation (LD) principle with a convex rate function J_h . This, of course, does not say much. However,

1) For repulsive potentials **(R)**, it is always the case that the probability measures \mathbb{P}_n^h are asymptotically concentrated on ballistic trajectories: For every $h \neq 0$ there exist $\bar{v} = \bar{v}_h \in \mathbb{R}^d \setminus \{0\}$, a constant $\kappa > 0$ and a small ϵ ($\epsilon < \|\bar{v}_h\|$), such that

$$\mathbb{P}_n^h \left(\frac{D(\gamma)}{n} \notin B_\epsilon(\bar{v}) \right) \leq e^{-\kappa n}, \quad (1.9)$$

where $B_\epsilon(\bar{v}) = \{u : |u - \bar{v}| < \epsilon\}$. Furthermore, the end-point $\gamma(n)$ complies with the following strong local limit type description: The rate function J_h is real analytic and strictly convex on $B_\epsilon(\bar{v}_h)$ with a non-degenerate quadratic minimum at \bar{v}_h . Moreover, there exists a strictly positive real analytic function G on $B_\epsilon(\bar{v}_h)$ such that

$$\mathbb{P}_n^h \left(\frac{D(\gamma)}{n} = u \right) = \frac{G(u)}{\sqrt{(n)^d}} e^{-nJ_h(u)} (1 + o(1)), \quad (1.10)$$

uniformly in $u \in B_\epsilon(\bar{v}_h) \cap \mathbb{Z}^d/n$. In particular, the displacement $D(\gamma)$ obeys under \mathbb{P}_n^h a local CLT and local moderate deviations on all possible scales.

2) In the (normalised) attractive case **(A) + (SL)**:

- If $h \in \text{int}(\mathbf{K}_{\lambda_0})$, then $D(\gamma)/n$ behaves sub-ballistically: Namely, the rate function J_h is bounded below in a neighbourhood of the origin as $J_h(u) \geq \alpha\|u\|$ for some $\alpha = \alpha(h) > 0$.
- If, on the other hand, $h \notin \mathbf{K}_{\lambda_0}$, then both (1.9) and the local limit description (1.10) hold.

Remark 1. *It remains an open question to determine what happens when $h \in \partial\mathbf{K}_{\lambda_0}$. Nevertheless, we shall show that in this case the rate function satisfies $J_h(0) = 0$, and thus no ballistic behaviour in the sense of (1.9) is to be expected. It still remains to understand whether the sub-ballistic to ballistic transition is of first order. One way to formulate this question is: Assume that $h \in \partial\mathbf{K}_{\lambda_0}$; does $\liminf_{\epsilon \rightarrow 0} \|\bar{v}_{(1+\epsilon)h}\| > 0$ hold or not? In (Mehra and Grassberger, 2002) it is claimed on the basis of simulations that the transition is of first order in dimensions $d \geq 2$ whereas it is of second order in $d = 1$.*

In the sequel, values of *positive* constants $\delta, \epsilon, \nu, c, C_1, c_2, \dots$ may vary from section to section.

1.5 Acknowledgements

This work was partly supported by the Swiss NSF grant #200020-113256.

2 Coarse Graining

Let $\lambda > \lambda_0$. In this section we are going to develop a rough description of typical paths which contribute to $\mathbb{H}_\lambda(x)$. Their contribution is going to be measured in terms of the probability distribution

$$\mathbb{P}_\lambda^x(\gamma) = \frac{W_\lambda(\gamma)}{\mathbb{H}_\lambda(x)}$$

on \mathcal{H}_x . Our results will be particularly relevant in the asymptotic regime $\|x\| \rightarrow \infty$.

The key idea behind the renormalisation is that although on the microscopic scale paths γ are entitled to wiggle as much as they wish, on large but yet finite scales they exhibit a much more rigid behaviour and, in a sense, go ballistically towards x .

The skeleton scale K is going to be chosen the same for all x . Given such K and a path $\gamma \in \mathcal{H}_x$ we shall use $\hat{\gamma}_K$ for the K -skeleton of γ . The construction of $\hat{\gamma}_K$ will be different for repulsive and attractive interactions, but in both cases $\hat{\gamma}_K$ will enjoy the following two properties:

(P1) γ passes through *all* the vertices of $\hat{\gamma}_K$.

(P2) If η is a portion of γ which connects two vertices u and v of $\hat{\gamma}_K$ and η does not pass through any other vertex of $\hat{\gamma}_K$, then

$$\eta \subseteq K\mathbf{U}_\lambda(u) \cup K\mathbf{U}_\lambda(v), \tag{2.1}$$

where \mathbf{U}_λ is the unit ball in the ξ_λ norm.

Below we shall rely on the following inequality which holds for all the models we consider: Let $\lambda > \lambda_0$ be fixed. There exists a sequence $\epsilon_K \rightarrow 0$, such that

$$\mathbb{H}_\lambda(u) \leq e^{-\xi_\lambda(u)(1-\epsilon_K)}, \tag{2.2}$$

uniformly in K and in $u \notin K\mathbf{U}_\lambda$.

Indeed, in the attractive case (2.2) follows from super-multiplicativity of $\mathbb{H}_\lambda(x)$ (with $\epsilon_K \equiv 0$). In the repulsive case (2.2) follows from the estimate (A.2) of Appendix.

Figure 1: The construction of the K -skeleton in the repulsive case.

2.1 Skeletons in the repulsive case

Let us fix a scale K . The K -skeleton $\hat{\gamma}_K$ of $\gamma = (\gamma(0), \dots, \gamma(n)) \in \mathcal{H}_x$ is constructed as follows (see Fig. 1):

STEP 0. Set $u_0 = 0$, $\tau_0 = 0$ and $\hat{\gamma}_K = \{u_0\}$. Go to STEP 1.

STEP (l+1). If $(\gamma(i_l), \dots, \gamma(n)) \subseteq K\mathbf{U}_\lambda(u_l)$ then stop. Otherwise set

$$\tau_{l+1} = \min \{j > \tau_l : \gamma(j) \notin K\mathbf{U}_\lambda(u_l)\}.$$

Define $u_{l+1} = \gamma(\tau_{l+1})$, update $\hat{\gamma}_K = \hat{\gamma}_K \cup \{u_{l+1}\}$ and go to STEP (l+2). \square

Given a skeleton $\hat{\gamma}_K = (0, u_1, \dots, u_m)$ we use $\#(\hat{\gamma}_K) = m$ for the number of *full* K -steps. If γ is compatible with $\hat{\gamma}_K$, then it is decomposable as the concatenation,

$$\gamma = \gamma_1 \cup \gamma_2 \cup \dots \cup \gamma_m \cup \gamma_{m+1},$$

where $\gamma_l : u_{l-1} \mapsto u_l$ for $l = 1, \dots, m$ and $\gamma_{m+1} : u_{m+1} \mapsto x$. By construction, $\gamma_l \in \mathcal{H}_{u_l - u_{l-1}}$. Since we are in the repulsive case,

$$W_\lambda(\gamma) \leq \prod_1^{m+1} W_\lambda(\gamma_l) \quad (2.3)$$

Therefore, the probability of appearance of $\hat{\gamma}_K$ is bounded above as (see (2.2) for the second inequality),

$$\mathbb{P}_\lambda^x(\hat{\gamma}_K) \leq \frac{\prod_1^m \mathbb{H}_\lambda(u_l - u_{l-1})}{\mathbb{H}_\lambda(x)} \leq \frac{e^{-mK(1-\epsilon_K)}}{\mathbb{H}_\lambda(x)}. \quad (2.4)$$

This formula is a key to a study of the geometry of typical skeletons and hence of typical paths. Its implications for path decomposition are discussed in detail in Section 3. Notice, however, that one immediate consequence is the following uniform exponential bound on the number of steps in typical skeletons: There exist $\nu = \nu(\lambda, d)$ and $C = C(\lambda, d)$ and a large finite scale $K_0 = K_0(\lambda, d)$, such that,

$$\mathbb{P}_\lambda^x \left(\#(\hat{\gamma}_K) > C \frac{\|x\|}{K} \right) \leq e^{-\nu \|x\|}, \quad (2.5)$$

uniformly in $K \geq K_0$ and $x \in \mathbb{Z}^d$. Indeed, the total number of m -step K -skeletons is bounded above as $\exp\{c_1(d, \lambda) \log K\}$, which, on large K scales, is suppressed by the extra $e^{-K(1-\epsilon_K)}$ per step price in (2.4).

Figure 2: The first stage of the construction of the K -skeleton in the attractive case (notice that $u_5 = v_5$ and $u_6 = v_6$ in this picture). In a second stage, one constructs skeletons for the (reversed) paths connecting u_k to v_k , using the algorithm for the repulsive case.

2.2 Skeletons in the attractive case

Since in the attractive case (2.3) does not hold we should proceed with more care. Accordingly our construction relies on the following fact: Assume that the path γ can be represented as a concatenation,

$$\gamma = \gamma_1 \cup \eta_1 \cup \gamma_2 \cup \dots \cup \gamma_m \cup \eta_m, \quad (2.6)$$

such that $\gamma_1, \dots, \gamma_m$ share at most one end-point. Then,

$$W_\lambda(\gamma) \leq \prod_{l=1}^m W_\lambda(\gamma_l) e^{\phi(1)} \cdot \prod_{k=1}^m e^{-\lambda|\eta_k|}. \quad (2.7)$$

For every $\lambda > \lambda_0$, (1.3) enables a comparison with a killed simple random walk. Consequently, since ξ_λ is an equivalent norm, there exists $\delta = \delta(\lambda, d) > 0$, such that

$$\sum_{\eta \in \mathcal{H}_u} e^{-\lambda|\eta|} \leq e^{-\delta K}, \quad (2.8)$$

uniformly in K and in $u \notin K\mathbf{U}_\lambda$.

In view of (2.7) and (2.8) it happens to be natural to construct skeletons $\hat{\gamma}_K$ as a union $\hat{\gamma}_K = \mathbf{t}_K \cup \mathbf{h}_K$, where \mathbf{t}_K is the trunk and \mathbf{h}_K is the set of hairs of $\hat{\gamma}_K$ (see Fig. 2). Let $\gamma \in \mathcal{H}_x$ and choose a scale K .

STEP 0. Set $u_0 = 0$, $\tau_0 = 0$ and $\mathbf{t}_0 = \{u_0\}$. Go to STEP 1.

STEP (1+1) If $(\gamma(\tau_l), \dots, \gamma(n)) \subseteq K\mathbf{U}_\lambda(u_l)$ then set $\sigma_{l+1} = n$ and stop. Otherwise, define

$$\begin{aligned} \sigma_{l+1} &= \min \{i > \tau_l : \gamma(i) \notin K\mathbf{U}_\lambda(u_l)\} \\ &\text{and} \\ \tau_{l+1} &= 1 + \max \{i > \tau_l : \gamma(i) \in K\mathbf{U}_\lambda(u_l)\}. \end{aligned}$$

Set $v_{l+1} = \gamma(\sigma_{l+1})$ and $u_{l+1} = \gamma(\tau_{l+1})$. Update $\mathbf{t}_K = \mathbf{t}_K \cup \{u_{l+1}\}$ and go to STEP (1+2) \square

Apart from producing \mathbf{t}_K the above algorithm leads to a decomposition of γ as in (2.6) with

$$\gamma_l = (\gamma(\tau_l), \dots, \gamma(\sigma_{l+1})) \quad \text{and} \quad \eta_l = (\gamma(\sigma_l), \dots, \gamma(\tau_l)).$$

The hairs \mathfrak{h}_K of $\hat{\gamma}_K$ take into account those η_l -s which are long on K -th scale. Recall that $\eta_l : v_l \mapsto u_l$. It is equivalent, but more convenient to think about η_l as of a reversed path from u_l to v_l . Then the l -th hair \mathfrak{h}_K^l of γ is constructed as follows: If $\eta_l \subseteq K\mathbf{U}_\lambda(u_l)$ then $\mathfrak{h}_K^l = \emptyset$. Otherwise, construct \mathfrak{h}_K^l of η_l following exactly the same rules as in the construction of K -skeletons in the repulsive case.

Putting everything together, using (2.7) and (2.8), we arrive to the following upper bound on the probability of a K -skeleton $\hat{\gamma}_K = \mathbf{t}_K \cup \mathfrak{h}_K$,

$$\mathbb{P}_\lambda^x(\mathbf{t}_K \cup \mathfrak{h}_K) \leq \frac{e^{-\#(\mathbf{t}_K)K(1-\phi(1)/K) - \delta K \#(\mathfrak{h}_K)}}{\mathbb{H}_\lambda(x)}, \quad (2.9)$$

where $\#(\mathfrak{h}_K) \triangleq \sum_1^m \#(\mathfrak{h}_K^l)$ is the total K -length of hairs attached to the trunk \mathbf{t}_K . As in the repulsive case, (2.9) leads to an exponential upper bound on the number of K -steps in the trunk \mathbf{t}_K : There exists a large finite scale $K_0 = K_0(\lambda, d)$ such that

$$\mathbb{P}_\lambda^x(\mathbf{t}_K) \leq \frac{e^{-\#(\mathbf{t}_K)K(1-\epsilon_K)}}{\mathbb{H}_\lambda(x)}, \quad (2.10)$$

for all $K \geq K_0$ and uniformly in x and \mathbf{t}_K . Consequently, there exist $\nu = \nu(\lambda, d)$ and $C = C(\lambda, d)$ such that,

$$\mathbb{P}_\lambda^x\left(\#(\mathbf{t}_K) > C \frac{\|x\|}{K}\right) \leq e^{-\nu\|x\|}, \quad (2.11)$$

uniformly in $K \geq K_0$ and $x \in \mathbb{Z}^d$. Furthermore, since the number of different ways to attach hairs \mathfrak{h}_K with $\#(\mathfrak{h}_K) = r$ to vertices of a trunk \mathbf{t}_K of cardinality $\#(\mathbf{t}_K) = m$ is bounded above as

$$e^{c_1 r \log K} \cdot \frac{1}{\max_p p^r (1-p)^m} \leq e^{c_2 r \log K + m/K},$$

formula (2.9) implies that

$$\mathbb{P}_\lambda^x\left(\#(\mathfrak{h}_K) = r; \#(\mathbf{t}_K) \leq C \frac{\|x\|}{K}\right) \leq e^{-\delta r K + c_3 \|x\| \log K/K} \max_{K \#(\mathbf{t}_K) \leq C \|x\|} \frac{e^{-K \#(\mathbf{t}_K)}}{\mathbb{H}_\lambda(x)}.$$

As we shall point out in the beginning of Section 3,

$$\limsup_{K \rightarrow \infty} \limsup_{\|x\| \rightarrow \infty} \frac{1}{\|x\|} \log \max_{K \#(\mathbf{t}_K) \leq C \|x\|} \frac{e^{-K \#(\mathbf{t}_K)}}{\mathbb{H}_\lambda(x)} = 0. \quad (2.12)$$

Consequently, for each $\epsilon > 0$ there exists a finite scale $K_0 = K_0(\epsilon, \lambda, d)$, such that

$$\mathbb{P}_\lambda^x\left(\#(\mathfrak{h}_K) > \epsilon \frac{\|x\|}{K}\right) \leq e^{-\epsilon \delta \|x\|/2}, \quad (2.13)$$

uniformly in $K \geq K_0$ and $x \in \mathbb{Z}^d$.

3 Irreducible decomposition of ballistic paths

In this section we derive an irreducible representation of typical (under \mathbb{P}_λ^x) paths $\gamma \in \mathcal{H}_x$. This irreducible representation has an effective 1D structure and it enables a local limit treatment of various observables over paths such as, e.g., the displacement $D(\gamma)$ along γ , or the number of steps $|\gamma|$ in γ . It should be kept in mind that in the framework of the theory we develop there are *many alternative* ways to define irreducible paths and, accordingly, to study statistics of other local patterns over γ .

In the sequel, given $x \in \mathbb{Z}^d$, we say that $h \in \partial\mathbf{K}_\lambda$ is dual to x if $(h, x) = \xi_\lambda(x)$. Of course, if h is dual to x , then h is dual to αx for any $\alpha > 0$. Thus it makes sense to talk about $\|x\| \rightarrow \infty$ for a fixed dual h .

3.1 Surcharge function and surcharge inequality

We shall now analyse the geometry of typical K -skeletons. In order to unify as much as possible our treatment of the repulsive and attractive cases, let us define the trunk \mathbf{t}_K of the skeleton $\hat{\gamma}_K$ in the repulsive case as being the skeleton itself, $\mathbf{t}_K = \hat{\gamma}_K$.

The basic quantity in the following analysis is the *surcharge function* of a trunk $\mathbf{t}_K = (u_0, \dots, u_m)$ defined by

$$\mathfrak{s}_h(\mathbf{t}_K) = \sum_{i=1}^m \mathfrak{s}_h(u_i - u_{i-1}),$$

where the function $\mathfrak{s}_h : \mathbb{R}^d \rightarrow \mathbb{R}_+$ is given by $\mathfrak{s}_h(y) = \xi_\lambda(y) - (h, y)$. Note that $\mathfrak{s}_h(y) = 0$ if and only if $h \in \partial\mathbf{K}_\lambda$ and y are dual directions. The surcharge measure \mathfrak{s}_h enters our skeleton calculus in the following fashion: By construction, $\xi_\lambda(u_i - u_{i-1}) \leq K + c_1(\lambda)$ for all K -steps of \mathbf{t}_K . As a result,

$$K\#(\mathbf{t}_K) \geq \sum (\xi_\lambda(u_i - u_{i-1}) - c_1(\lambda)) \geq \xi_\lambda(x) + \mathfrak{s}_h(\mathbf{t}_K) - c_1\#(\mathbf{t}_K).$$

Since we can restrict attention to $\#(\mathbf{t}_K) \leq C\|x\|/K$, (2.12) is an immediate corollary. Moreover, arguing similarly as in (2.4) and (2.10), we obtain that, for any $\epsilon > 0$ fixed,

$$\mathbb{P}_\lambda^x(\mathbf{t}_K) \leq e^{-\mathfrak{s}_h(\mathbf{t}_K)(1-o_K(1))},$$

uniformly in $\|x\|$ and in $\mathfrak{s}_h(\mathbf{t}_K) \geq \epsilon\|x\|$, with $\lim_{K \rightarrow \infty} o_K(1) = 0$. The following *surcharge inequality* is at the core of our method, allowing to reduce the characterisation of typical trunks to geometrical considerations.

Lemma 3.1. *For every small $\epsilon > 0$ there exists $K_0(d, \lambda, \epsilon)$ such that*

$$\mathbb{P}_\lambda^x(\mathfrak{s}_h(\mathbf{t}_K) > 2\epsilon\|x\|) \leq e^{-\epsilon\|x\|},$$

uniformly in $x \in \mathbb{Z}^d$, $h \in \partial\mathbf{K}_\lambda$ dual to x , and scales $K > K_0$.

Proof. By (2.5) and (2.11), we can assume that the trunk is admissible, that is $\#(\mathbf{t}_K) \leq C\|x\|/K$. Since the number of such trunks is bounded by

$$\exp\left(c_2(d, \lambda) \frac{\log K}{K} \|x\|\right),$$

we infer that

$$\mathbb{P}_\lambda^x(\mathfrak{s}_h(\mathbf{t}_K) > 2\epsilon\|x\|) \leq e^{-\nu\|x\|} + \exp\left(c_2(d, \lambda) \frac{\log K}{K} \|x\| - \mathfrak{s}_h(\mathbf{t}_K)(1 - o_K(1))\right) \leq e^{-\epsilon\|x\|},$$

as soon as K is chosen large enough. \square

Thanks to the surcharge inequality, we can exclude whole families of trunks simply by establishing a lower bound as above on their surcharge function.

3.2 Cone points of trunks

Let us fix $\delta \in (0, \frac{1}{3})$. For any $h \in \partial\mathbf{K}_\lambda$, we define the *forward cone* by

$$Y_\delta^>(h) = \{y \in \mathbb{Z}^d : \mathfrak{s}_h(x) < \delta\xi_\lambda(x)\},$$

and the *backward cone* by $Y_\delta^<(h) = -Y_\delta^>(h)$.

Given a trunk $\mathbf{t}_K = (u_0, \dots, u_m)$, we say that the point u_k is an (h, δ) -*forward cone point* if

$$\{u_{k+1}, \dots, u_m\} \subset u_k + Y_\delta^>(h).$$

Similarly, u_k is an (h, δ) -*backward cone point* if

$$\{u_0, \dots, u_{k-1}\} \subset u_k + Y_\delta^<(h).$$

Finally, u_k is an (h, δ) -*cone point* if it is both an (h, δ) -forward and an (h, δ) -backward cone point.

Proceeding now as in Section 2.6 of (Campanino et al., 2007), we prove that most vertices of typical trunks are (h, δ) -cone points. Let us denote by $\#_{h, \delta}^{\text{non-cone}}(\mathbf{t}_K)$ the number of those vertices in the trunk \mathbf{t}_K that are not (h, δ) -cone points.

Lemma 3.2. *Let $\delta \in (0, \frac{1}{3})$ be fixed. Then*

$$\mathfrak{s}_h(\mathbf{t}_K) \geq c_3 \delta K \#_{h, \delta}^{\text{non-cone}}(\mathbf{t}_K),$$

uniformly in $x \in \mathbb{Z}^d$, $h \in \partial\mathbf{K}_\lambda$ dual to x , and K large enough. In particular, the estimate

$$\mathbb{P}_\lambda^x\left(\#_{h, \delta}^{\text{non-cone}}(\mathbf{t}_K) \geq \epsilon \#(\mathbf{t}_K)\right) \leq e^{-c_4 \epsilon \|x\|},$$

holds uniformly in $x \in \mathbb{Z}^d$, $h \in \partial\mathbf{K}_\lambda$ dual to x , and K large enough.

3.3 Cone points of skeletons

In the repulsive case, the previous lemma provides all the control we need. In the attractive case, to which we restrict ourselves temporarily, it is also necessary to control the hairs. Let us start by extending the notion of (h, δ) -cone points from trunks to full skeletons: A point u_k of a trunk $\mathbf{t}_K = (u_0, \dots, u_m)$ is an (h, δ) -forward cone point of the skeleton $\hat{\gamma}_K = (\mathbf{t}_K \cup \mathfrak{h}_K)$ if

$$\hat{\gamma}_K \subset (u_k + Y_{2\delta}^>(h)) \cup (u_k + Y_{2\delta}^<(h)).$$

(Notice that we increased the aperture of the cone from δ to 2δ .) It readily follows (2.13) that most vertices of the trunk have no hair attached to them. Therefore, the only way an (h, δ) -cone point of \mathbf{t}_K may fail to be an (h, δ) -cone point of $\hat{\gamma}_K$ is when another vertex of the trunk has such a long hair attached to it that the latter exits the (enlarged) cone; in such a case, we say that the (h, δ) -cone point is *blocked*. Lemma 2.5 of (Campanino et al., 2007) implies that most vertices of the trunk are (h, δ) -cone points of $\hat{\gamma}_K$.

Lemma 3.3. *Let $\#_{h,\delta}^{\text{blocked}}(\hat{\gamma}_K)$ be the number of vertices of the trunk of $\hat{\gamma}_K$ that are not (h, δ) -cone points of $\hat{\gamma}_K$. Suppose that \mathbf{t}_K is an admissible trunk with $\#_{h,\delta}^{\text{non-cone}}(\mathbf{t}_K) < \epsilon \#(\mathbf{t}_K)$. Then there exists $c_5(d, \delta, \lambda) > 0$ such that*

$$\mathbb{P}_\lambda^x(\#_{h,\delta}^{\text{blocked}}(\hat{\gamma}_K) \geq \epsilon \#(\mathbf{t}_K) \mid \mathbf{t}_K) \leq e^{-c_5 \epsilon \|x\|},$$

uniformly in $x \in \mathbb{Z}^d$, $h \in \partial \mathbf{K}_\lambda$ dual to x , and K large enough.

3.4 Cone points of paths

We return now to the general case of attractive or repulsive potentials; in the latter case we identify the notions of cone points of trunks and skeletons, as these two notions coincide.

Now that the skeletons are under control, we can turn to the microscopic path itself. Let $\gamma = (\gamma(0), \dots, \gamma(n)) \in \mathcal{H}_x$. We say that $\gamma(k)$ is an (h, δ) -cone point of γ if

$$\gamma \subset (\gamma(k) + Y_{3\delta}^>(h)) \cup (\gamma(k) + Y_{3\delta}^<(h)).$$

Notice that we increased again the aperture of the cone to 3δ . Notice also that we tacitly assume that $Y_{3\delta}^>(h)$ contains a lattice direction.

Proceeding as in Section 2.7 of (Campanino et al., 2003), we can show that, up to exponentially small \mathbb{P}_λ^x -probabilities, a uniformly strictly positive fractions of the (h, δ) -cone points of the trunk of $\hat{\gamma}_K$ are actually (h, δ) -cone points of the path.

Theorem 3.1. *Let $\#_{h,\delta}^{\text{cone}}(\gamma)$ be the number of (h, δ) -cone points of γ . There exist $\delta \in (0, \frac{1}{3})$ and two positive numbers c and ν , depending only on d, δ and λ , such that*

$$\mathbb{P}_\lambda^x(\#_{h,\delta}^{\text{cone}}(\gamma) < c \|x\|) \leq e^{-\nu \|x\|},$$

uniformly in $x \in \mathbb{Z}^d$, $h \in \partial \mathbf{K}_\lambda$ dual to x , and K large enough.

Remark 2. *Observe that the above estimate still holds true (possibly for a smaller constant ν) when x is replaced by an arbitrary site $y \in Y_\delta^>(h)$.*

3.5 Decomposition of paths into irreducible pieces

With the help of the Theorem 3.1, we can finally construct the desired decomposition of typical ballistic paths into irreducible pieces.

A path $\gamma = (\gamma(0), \dots, \gamma(n))$ is said to be (h, δ) -backward irreducible if $\gamma(n)$ is the only (h, δ) -cone point of γ . Similarly, γ is said to be (h, δ) -forward irreducible if $\gamma(0)$ is the only (h, δ) -cone point of γ . Finally, γ is said to be irreducible if $\gamma(0)$ and $\gamma(n)$ are the only (h, δ) -cone points of γ .

Let Ω_L, Ω and Ω_R be the corresponding sets of such irreducible paths.

Figure 3: The decomposition of a path into irreducible components.

In view of Theorem 3.1, we can restrict our attention to paths possessing at least $c\|x\|$ (h, δ) -cone points, at least when $\|x\|$ is sufficiently large. We can then unambiguously decompose λ into irreducible sub-paths,

$$\gamma = \omega_L \cup \omega_1 \cup \cdots \cup \omega_m \cup \omega_R. \quad (3.1)$$

We thus have the following expression

$$e^{(h,x)}\mathbb{H}_\lambda(x) = O\left(e^{-\nu\|x\|}\right) + \sum_{m \geq c\|x\|} \sum_{\omega_L \in \Omega_L} \sum_{\omega_1, \dots, \omega_m \in \Omega} \sum_{\omega_R \in \Omega_R} W_{h,\lambda}(\gamma) \mathbb{I}_{\{D(\gamma)=x\}}. \quad (3.2)$$

In fact, since $e^{(h,y)}\mathbb{H}_\lambda(y) \asymp e^{-\nu\|y\|}$, we, in view of Remark 2, infer that, perhaps for a smaller choice of $\nu > 0$,

$$e^{(h,y)}\mathbb{H}_\lambda(y) = O\left(e^{-\nu\|y\|}\right) + \sum_{m \geq c\|y\|} \sum_{\omega_L \in \Omega_L} \sum_{\omega_1, \dots, \omega_m \in \Omega} \sum_{\omega_R \in \Omega_R} W_{h,\lambda}(\gamma) \mathbb{I}_{\{D(\gamma)=y\}}. \quad (3.3)$$

uniformly in $y \in \mathbb{Z}^d$.

3.6 Probabilistic structure of the irreducible decomposition

We shall treat Ω , Ω_L and Ω_R as probability spaces. In this way various path observables such as, e.g., $D(\omega)$ or $|\omega|$ will be naturally interpreted as random variables. First of all let us try to rewrite the weights of concatenated paths in the product form,

$$W_{h,\lambda}(\gamma) = W_{h,\lambda}(\omega_L \cup \omega_1 \cup \cdots \cup \omega_m \cup \omega_R) = \hat{W}_{h,\lambda}(\omega_L) \hat{W}_{h,\lambda}(\omega_R) \prod_l \hat{W}_{h,\lambda}(\omega_l) \quad (3.4)$$

If the potential Φ depends on bond local times only, then $\hat{W}_{h,\lambda} = W_{h,\lambda}$ qualifies. However, when Φ depends on site local times, such a choice would imply overcounting of local times at end-points. In that case, we thus set $\hat{W}_{h,\lambda}(\omega) = e^{\phi(1)}W_{h,\lambda}(\omega)$ for $\omega \in \Omega_L$ and $\omega \in \Omega$, and $\hat{W}_{h,\lambda} = W_{h,\lambda}$ on Ω_R . Evidently (3.4) is satisfied. Accordingly, we can rewrite (3.3) as

$$\begin{aligned} e^{(h,y)}\mathbb{H}_\lambda(y) &= O\left(e^{-\nu\|y\|}\right) \\ &+ \sum_{m \geq c\|y\|} \sum_{\omega_L \in \Omega_L} \sum_{\omega_1, \dots, \omega_m \in \Omega} \sum_{\omega_R \in \Omega_R} \hat{W}_{h,\lambda}(\omega_L) \hat{W}_{h,\lambda}(\omega_R) \prod_1^m \hat{W}_{h,\lambda}(\omega_l) \mathbb{I}_{\{D(\gamma)=y\}}. \end{aligned} \quad (3.5)$$

uniformly in $y \in \mathbb{Z}^d$. Since the sums over ω_L and ω_R converge (by Theorem 3.1), and

$$\mathbf{K}_\lambda = \overline{\left\{ h \in \mathbb{R}^d : \sum_{y \in \mathbb{Z}^d} e^{(h,y)} \mathbb{H}_\lambda(y) < \infty \right\}},$$

it follows that $h \in \partial \mathbf{K}_\lambda$ if and only if $\sum_{\omega \in \Omega} \hat{W}_{h,\lambda}(\omega) = 1$, and thus $\hat{W}_{h,\lambda}$ is a probability measure on Ω . Let us use the notation $\mathbb{Q}^{h,\lambda} = \hat{W}_{h,\lambda}$ to stipulate this fact. Similarly we shall use the notation $\mathbb{Q}_L^{h,\lambda}$ and $\mathbb{Q}_R^{h,\lambda}$ for the values of $\hat{W}_{h,\lambda}$ on respectively Ω_L and Ω_R .

In general $\mathbb{Q}_L^{h,\lambda}$ and $\mathbb{Q}_R^{h,\lambda}$ are not probability measures. However, together with $\mathbb{Q}^{h,\lambda}$, they display exponential tails both in the displacement variable $D(\omega)$ and in the number of steps $|\omega|$ (as well as in many other path observables of interest). Indeed, as follows from Theorem 3.1 and in view of the $Y_{3\delta}(h)$ -confinement properties of irreducible paths, all three measures in question already display exponential tails in the displacement variable $D(\omega)$. On the other hand, the weights $\hat{W}_{h,\lambda}$ are bounded above as

$$\hat{W}_{h,\lambda}(\omega) \leq e^{\|h\| \|D(\omega)\| - \lambda|\omega| + \phi(1)}.$$

Consequently, there exists $c_6 = c_6(\lambda, d)$, such that

$$\hat{W}_{h,\lambda}(\|D(\omega)\| = \ell, |\omega| > 2(\ell\|h\| + \phi(1))) \leq c_6 e^{-\ell\|h\|(\lambda - \lambda_0)}.$$

Together with the already established exponential tails of $D(\omega)$, this readily implies exponential tails for the variable $|\omega|$ as well. Exactly the same line of reasoning applies to $\mathbb{Q}_L^{h,\lambda}$ and $\mathbb{Q}_R^{h,\lambda}$.

We use $\mathbb{Q}_m^{h,\lambda}$ for the product probability measure on $\times_1^m \Omega$. Then (3.5) in its final form looks like

$$e^{(h,y)} \mathbb{H}_\lambda(y) = O\left(e^{-\nu\|y\|}\right) + \sum_{m \geq c\|y\|} \mathbb{Q}_L^{h,\lambda} \star \mathbb{Q}_R^{h,\lambda} \star \mathbb{Q}_m^{h,\lambda} \left(D(\omega_L) + D(\omega_R) + \sum_1^m D(\omega_l) = y \right). \quad (3.6)$$

Similarly, let F be some functional on paths, e.g., $F(\gamma) = |\gamma|$ or, for a change, $F(\gamma) = \sum_x \mathbb{1}_{\{t_x(\gamma) > 1\}}$. We then have the following expression for the restricted partition functions,

$$e^{(h,y)} \mathbb{H}_\lambda(y; F(\gamma) = f) = O\left(e^{-\nu\|y\|}\right) + \sum_{m \geq c\|y\|} \mathbb{Q}_L^{h,\lambda} \star \mathbb{Q}_R^{h,\lambda} \star \mathbb{Q}_m^{h,\lambda} (D(\gamma) = y; F(\gamma) = f). \quad (3.7)$$

The point is that, for good local functionals F such as in the two instances above, sharp asymptotics simply follow from local limit properties of the product measure $\mathbb{Q}_m^{h,\lambda}$.

Note that a very similar analysis applies for partition functions $\mathbb{D}_\lambda(\cdot)$. In particular, (3.7) holds for $\mathbb{D}_\lambda(y; F(\gamma) = f)$ with the very same measures $\mathbb{Q}_L^{h,\lambda}$, $\mathbb{Q}_R^{h,\lambda}$ and the appropriate modification of $\mathbb{Q}_R^{h,\lambda}$.

4 Proof of the main result

4.1 Large deviation rate function

Since

$$\Lambda(h) \triangleq \lim_{n \rightarrow \infty} \frac{1}{n} \log Z_n^h$$

is well defined (either by sub- or by super-additivity) and the distribution of the displacement per step $D(\gamma)/n$ under \mathbb{P}_n^h is certainly exponentially tight, the random variables $D(\gamma)/n$ satisfy a LD principle with rate function

$$J_h(u) = \sup_g \{(g, u) - \Lambda_h(g)\},$$

where $\Lambda_h(g) = \Lambda(h + g) - \Lambda(h)$.

We claim that:

$$\Lambda \equiv \lambda_0 \quad \text{on } \mathbf{K}_{\lambda_0}. \quad (4.1)$$

Consequently, if $h \in \text{int}(\mathbf{K}_{\lambda_0})$, then $\Lambda_h \equiv 0$ in a neighbourhood of the origin and hence there exists $\alpha = \alpha(h)$ such that $J_h(u) \geq \alpha\|u\|$, which is the sub-ballistic part of our Main Result.

Furthermore, we claim that if $h \notin \mathbf{K}_{\lambda_0}$, then Λ is real analytic and strictly convex in a neighbourhood of h . In addition,

$$\bar{v}_h = \nabla\Lambda(h) \neq 0 \quad \text{and} \quad d^2\Lambda(h) \text{ is non-degenerate.} \quad (4.2)$$

In fact, for $h \notin \mathbf{K}_{\lambda_0}$, we shall see that the log-moment generating function satisfies $\Lambda(h) = \lambda(h)$ with $\lambda = \lambda(h)$ being recovered from $h \in \partial\mathbf{K}_\lambda$. Since $\mathbf{K}_{\lambda_0} = \cap_{\lambda > \lambda_0} \mathbf{K}_\lambda$, (4.1) is an immediate consequence: Indeed, since Λ is convex and, by Jensen inequality, $Z_n^h \geq Z_n \asymp e^{\lambda_0 n}$, it satisfies $\Lambda \geq \lambda_0$.

For the rest of this section we shall, therefore, focus on the case $h \notin \mathbf{K}_{\lambda_0}$.

4.2 Surface $\lambda = \lambda(h) = \Lambda(h)$

Our next task is to explain (4.2). Let $\lambda > \lambda_0$ and $h \in \partial\mathbf{K}_\lambda$. As we shall see below, there exists $\Psi(h) > 0$, such that,

$$e^{-\lambda n} Z_n^h = \sum_\gamma W_{h,\lambda}(\gamma) = \Psi(h) (1 + o(1)). \quad (4.3)$$

This immediately implies that $\Lambda(h) = \lambda$. Let us for the moment accept (4.3) as an a priori lower bound on $e^{-\lambda n} Z_n^h$ (see the paragraph after (4.4) below). Then we are able to rule out \mathbb{P}_n^h -negligible x -s as follows:

1) Let $0 < l < \lambda - \lambda_0$. Then,

$$e^{-\lambda n} Z_n^h ((h, \gamma(n)) \leq ln) \leq e^{-(\lambda-l)n} Z_n.$$

Since $Z_n \asymp e^{\lambda_0 n}$, the latter expression is exponentially small and we can ignore x -s such that $(h, x) \leq ln$.

2) Let $(h, x) > ln$, but $x \notin Y_\delta^>(h)$ (see Section 3). Then $Z_{n,x}^{h,\lambda} \leq Z_x^{h,\lambda} \leq e^{-\nu\|x\|}$, and, consequently, we can ignore such x -s as well.

It remains to consider $x \in Y_\delta^>(h)$ with $\|x\| > ln/\|h\| \triangleq c_1n$. For such x -s, (3.7), or rather its modification in the case of \mathbb{D}_λ -partition functions, implies that

$$\begin{aligned} Z_{n,x}^{h,\lambda} &= \sum_{\substack{\gamma \in \mathcal{D}_x \\ |\gamma|=n}} W_{h,\lambda}(\gamma) \\ &= O(e^{-c_1\nu n}) + \sum_{m \geq c\|x\|} \mathbb{Q}_L^{h,\lambda} \star \mathbb{Q}_R^{h,\lambda} \star \mathbb{Q}_m^{h,\lambda}(D(\gamma) = x, |\gamma| = n) \\ &= C'(h) \sum_{m \geq c\|x\|} \mathbb{Q}_m^{h,\lambda} \left(\sum_{i=1}^m (D(\omega_i), |\omega_i|) = (x, n) \right), \end{aligned} \quad (4.4)$$

where in the last line, apart from ignoring the $O(e^{-c_1\nu n})$ term, we have (already anticipating local limit behaviour under $\mathbb{Q}_m^{h,\lambda}$) summed out the terms involving $\mathbb{Q}_L^{h,\lambda}$ and $\mathbb{Q}_R^{h,\lambda}$. And indeed, since the random vector $V(\omega) = (D(\omega), |\omega|)$ has exponential moments under $\mathbb{Q}^{h,\lambda}$, we can apply the classical local CLT to (4.4), which, after summing up with respect to x , yields the lower bound in (4.3), thereby justifying the conclusions 1) and 2) above.

Let now $g \in \partial\mathbf{K}_\mu$ with (g, μ) being sufficiently close to (h, λ) , say,

$$|\lambda - \mu| + \|g - h\| < \frac{1}{2} \min \{\nu, \lambda - l\}.$$

Then 1) and 2) above still describe \mathbb{P}_n^g -negligible x -s. Moreover, the (g, μ) -modification of (4.4) still holds: For $x \in Y_\delta^>(h)$ with $\|x\| \geq c_1n$,

$$Z_{n,x}^{g,\mu} (1 + o(1)) = C'(g) \sum_{m \geq c_1\|x\|} \mathbb{Q}_m^{h,\lambda} \left(\sum_{i=1}^m (D(\omega_i), |\omega_i|) = (x, n) \right) e^{(g-h,x) - (\mu-\lambda)n}.$$

(The prefactor $C'(g)$ coming as before from the summation over ω_L and ω_R .) Since we have employed the very same sets of irreducible paths, the positive function $C'(g)$ is real analytic. Now, using an argument similar to the one in Subsection 3.6, together with the fact that the lower bound in (4.3) holds for (g, μ) as well, we deduce that

$$\mathbb{Q}^{h,\lambda} \left(e^{(g-h,D(\omega)) - (\mu-\lambda)|\omega|} \right) = 1.$$

In other words, define

$$F(g, \mu) = \log \sum_{\omega \in \Omega} e^{(g,D(\omega)) - \mu|\omega|} W(\omega).$$

We have proved:

Lemma 4.1. *Let $\lambda > \lambda_0$ and $h \in \partial\mathbf{K}_\lambda$. Then there exists $\rho > 0$ such that the graph of the function $\mu = \Lambda(g)$ over $B_\rho(h)$ is implicitly given by*

$$F(g, \mu) = 0.$$

Since the distribution of the random vector V under $\mathbb{Q}^{h,\lambda}$ is obviously non-degenerate and has finite exponential moments in a neighbourhood of the origin, (4.2) follows. Furthermore, there exists $\epsilon > 0$ such that

$$B_\epsilon(\bar{v}_h) \subset \cup_{g \in B_\rho(h)} \nabla \Lambda(g). \quad (4.5)$$

□

4.3 Local limit result in the ballistic regime

We already know that under \mathbb{P}_n^h the average displacement $D(\gamma)/n$ satisfies a LD principle with strictly convex rate function J_h . Thereby, (1.9) is justified. Let us restrict our attention to $x \in B_{\epsilon n}(n\bar{v}_h)$ and go back to (4.4). Obviously, $(\bar{v}_h, 1)$ is parallel to $\mathbf{z} = (\bar{w}, \bar{t}) \triangleq \mathbb{Q}^{h,\lambda}((D(\omega), |\omega|))$. Set $x = \lfloor n\bar{v}_h \rfloor$. By the local CLT and Gaussian summation formula applied to (4.4),

$$Z_{n,x}^{h,\lambda} = \frac{C(h)}{\sqrt{n^d}} (1 + o(1)). \quad (4.6)$$

Let $y \in \mathbf{B}_{n\epsilon}(n\bar{v}_h) \cap \mathbb{Z}^d$ and $u \triangleq y/n \in B_\epsilon(\bar{v}_h)$. By (4.5), we can find $g \in B_\rho(h)$ such that $u = \nabla \Lambda(g)$. Set $\mu = \Lambda(g)$ and $y = \lfloor nu \rfloor$. As in (4.6),

$$Z_{n,y}^{g,\mu} = \frac{C(g)}{\sqrt{n^d}} (1 + o(1)), \quad (4.7)$$

where C is a positive real analytic function on $B_\rho(h)$. On the other hand,

$$Z_{n,y}^{h,\lambda} = e^{-n((g-h,u) + \Lambda(h) - \Lambda(g))} Z_{n,y}^{g,\mu}.$$

It remains to notice that

$$(g - h, u) + \Lambda(h) - \Lambda(g) = J_h(u).$$

Since C in (4.7) is analytic (continuous would be enough) and J_h has quadratic minimum at \bar{v}_h , the partition function asymptotics (4.3) follows from Gaussian summation formula. (1.10) is proved. \square

5 Perturbations by small potentials and statistics of patterns

Let Φ be either an attractive or a repulsive potential of the type considered above, $\lambda > \lambda_0$ and $h \in \partial \mathbf{K}_\lambda$. Let $\mathcal{U}_h \subset \mathbb{R}^d$ be a neighbourhood of h .

We would like to consider perturbations of Φ of the form,

$$\tilde{\Phi}(\gamma) = \Phi(\gamma) + R(\gamma, h). \quad (5.1)$$

We shall assume that for each fixed γ the function $g \mapsto R(\gamma, g)$ is analytic on \mathcal{U}_h and that it is appropriately negligible: For some ϵ sufficiently small,

$$\sup_{g \in \mathcal{U}_h} |R(\gamma, g)| \leq \epsilon |\gamma|, \quad (5.2)$$

simultaneously for all γ .

Furthermore, we shall assume that the perturbation R is in some sense local. This could be quantified on various levels of generality and, in order to fix ideas, we shall restrict our attention to the following case: For every $g \in \mathcal{U}_h$,

$$R(\gamma_1 \cup \dots \cup \gamma_m, g) = \sum_1^m R(\gamma_i, g), \quad (5.3)$$

whenever $\gamma_1, \dots, \gamma_m$ are edge disjoint.

5.1 An example

An immediate example is a random walk with small edge reinforcement. Set $F \equiv 0$. For a path $\gamma = (x_0, x_1, x_2, \dots)$ define the running local times on *unoriented* bonds,

$$l_b^t(\gamma) = \sum_{j=0}^{t-1} \mathbb{1}_{\{b=(x_j, x_{j+1})\}}.$$

Let $\beta : \mathbb{N} \mapsto \mathbb{R}_+$ be a non-decreasing bounded concave function with $\beta(\infty) = \epsilon$. Set

$$R(\gamma, h) = - \sum_{t=0}^{|\gamma|-1} \log \mathbb{E} \exp \left\{ \beta(l_{x_i, x_i + X_h}^t(\gamma)) - \beta(l_{(x_i, x_{i+1})}^t(\gamma)) \right\},$$

where the random variable X_h is distributed as the step of a simple random walk with drift h .

5.2 Ballistic behaviour and local limit theory

Let \tilde{Z}_n^h be the partition function which corresponds to the perturbed interaction (5.1). We claim that the following generalisation of (4.3) holds:

Theorem 5.1. *Let Φ , $\lambda > \lambda_0$ and $h \in \partial \mathbf{K}_\lambda$ be fixed. Then one can choose a number $\epsilon_0 = \epsilon_0(h, \Phi) > 0$, a continuous function $\rho : [0, \epsilon_0] \mapsto \mathbb{R}_+$ with $\rho(0) = 0$ and a neighbourhood \mathcal{U}_h of h , so that:*

For any $\epsilon \leq \epsilon_0$ and for any (analytic) perturbation $\tilde{\Phi} = \Phi + R$ of Φ satisfying (5.3) and (5.2) above, there exist an analytic function f with

$$\sup_{g \in \mathcal{U}_h} |f(g)| \leq \rho(\epsilon), \quad (5.4)$$

and a positive analytic function $\tilde{\Psi}$ on \mathcal{U}_h , such that the following asymptotics holds

$$e^{-\lambda(g)n} \tilde{Z}_n^g = \tilde{\Psi}(g) e^{nf(g)} (1 + o(1)), \quad (5.5)$$

uniformly in $g \in \mathcal{U}_h$. The function f can be recovered from the following implicit relation,

$$\log \mathbb{Q}^{g, \lambda(g)} \left(e^{f(g)|\omega| - R(\omega, g)} \right) = 0. \quad (5.6)$$

The proof and the implications of the above theorem essentially boil down to a rerun of the arguments employed in the pure (repulsive or attractive) cases: The crux of the matter is that under assumption (5.2) the random variable $R(\omega, h)$ on the probability space $(\Omega, \mathbb{Q}^{h, \lambda})$ has exponential tails, whereas under assumption (5.3) all the relevant asymptotics are settled via local limit theorems for independent random variables. Let us briefly reiterate the principal steps involved:

STEP 1 Assume (5.5) as an a priori lower bound on $e^{-\lambda(g)n} \tilde{Z}_n^g$ and use it to rule out trajectories $\gamma = (\gamma(0), \dots, \gamma(n))$ which fail to comply with:

- 1) $\min \{(\gamma(n), g), \|\gamma(n)\|\} \geq c_1 n$ and $\gamma_n \in Y_\delta^>(h)$.

2) γ has at least $m \geq c_2 n$ irreducible pieces,

$$\gamma = \omega_L \cup \omega_1 \cup \dots \cup \omega_m \cup \omega_R.$$

STEP 2 By Assumption (5.2), the random variables $D(\omega)$ and $|\omega|$ have exponential tails under the modified measures $\tilde{\mathbb{Q}}^{g, \lambda(g)}$,

$$\tilde{\mathbb{Q}}^{g, \lambda(g)}(\omega) = \frac{\mathbb{Q}^{g, \lambda(g)}(\omega) e^{-R(\omega, g)}}{\mathbb{Q}^{g, \lambda(g)}(e^{-R(\cdot, g)})}.$$

Consequently, both the lower bound in (5.5) and then (5.5) itself follow from the local limit analysis of i.i.d. sums $\sum_1^m V_i$, where $V(\omega) = (D(\omega), |\omega|)$. In particular, the limiting log-moment generating functions

$$\tilde{\Lambda}(g) = \lim_{n \rightarrow \infty} \frac{\log \tilde{Z}_n^g}{n} \triangleq \lambda(g) + f(g),$$

are analytic on \mathcal{U}_h , whereas the asymptotic speed $\tilde{v}_n = \nabla \tilde{\Lambda}(h)$ has a positive projection on h by STEP 1. The local limit description of the distribution of the end-point $\gamma(n)$ under the perturbed measure $\tilde{\mathbb{P}}_n^h$ follows exactly as in the pure (repulsive or attractive) case. In particular, we arrive to the following local limit description of ballistic behaviour under $\tilde{\mathbb{P}}_n^h$: There exists $\epsilon' > 0$, such that:

- Outside $B_{\epsilon'}(\tilde{v}_h)$,

$$\tilde{\mathbb{P}}_n^h \left(\frac{D(\gamma)}{n} \notin B_{\epsilon'}(\tilde{v}_h) \right) \leq e^{-c_3 n}.$$

- For $nu \in B_{n\epsilon'}(n\tilde{v}_h) \cap \mathbb{Z}^d$,

$$\tilde{\mathbb{P}}_n^h(D(\gamma) = nu) = \frac{\tilde{G}(u)}{\sqrt{n^d}} e^{-n\tilde{J}_h(u)} (1 + o(1)),$$

where the rate function \tilde{J}_h on $B_{\epsilon'}(\tilde{v}_h)$ is quadratic at its unique minimum \tilde{v}_h .

□

5.3 Statistics of finite patterns and local observables

A finite pattern is a fixed nearest neighbour (and self-avoiding in case of SAW-s) path,

$$\eta = (u_0, \dots, u_p).$$

For example, we may take η as an elementary loop,

$$\eta = (0, \mathbf{e}_1, \mathbf{e}_1 + \mathbf{e}_2, \mathbf{e}_2). \quad (5.7)$$

Given a trajectory γ define $N_\eta(\gamma)$ as the number of times η is re-incarnated in γ ,

$$N_\eta(\gamma) = \sum_{l=0}^{|\gamma|-p} \mathbb{1}_{\{(\gamma(l), \dots, \gamma(l+p)) \stackrel{\text{m}}{=} \eta\}}$$

where $\stackrel{\text{m}}{=}$ means matching up to a shift. Obviously, $N(\gamma) \leq |\gamma|$. Also, in the case of (5.7),

$$N_\eta(\gamma) = N_\eta(\omega_L) + N_\eta(\omega_1) + \cdots + N_\eta(\omega_m) + N_\eta(\omega_R), \quad (5.8)$$

whenever γ is given in its irreducible representation (3.1).

For general patterns η the relation (5.8) does not necessarily hold for the particular irreducible decomposition which was constructed in Section 3. We could not have worried less: First of all given *any* finite pattern η we could have adjusted the notion of irreducible decomposition in such a way that (5.8) would become true. Furthermore, the import of (5.8) is a possibility to work with independent random variables. In the situation we consider here sums of finitely dependent variables have qualitatively the same local asymptotics as sums of i.i.d.-s. So, for the sake of exposition, let us assume that η satisfies (5.8).

But then, given some small $\delta > 0$, $R(\gamma) = \delta N_\eta(\gamma)$ qualifies as a small perturbation of the type considered in the preceding section. Accordingly, we are in a position to develop a standard local limit analysis of restricted partition functions of the type

$$Z_n^h(N_\eta(\gamma) = \lfloor nx \rfloor).$$

Theorem 5.2. *Let η be a finite pattern, $\lambda > \lambda_0$ and $h \in \partial \mathbf{K}_\lambda$. Then there exist $x_\eta \in (0, 1)$, $\epsilon > 0$, $\nu > 0$ and a rate function J_h^η on $(x_\eta - \epsilon, x_\eta + \epsilon)$ with quadratic minimum at x_η , such that,*

$$\mathbb{P}_n^h \left(\left| \frac{N_\eta(\gamma)}{n} - x_\eta \right| \geq \epsilon \right) \leq e^{-\nu n},$$

and, for $x \in (x_\eta - \epsilon, x_\eta + \epsilon)$,

$$\mathbb{P}_n^h(N_\eta(\gamma) = \lfloor nx \rfloor) = \frac{G_\eta(x)}{\sqrt{n}} e^{-nJ_h^\eta(x)} (1 + o(1)),$$

where, of course, G_η is a positive real analytic function on $[x_\eta - \epsilon, x_\eta + \epsilon]$

Note that we have used only $|N_\eta(\gamma)| \leq |\gamma|$ and (5.8). Therefore, the above theorem holds for a wider class of path observables, as for example,

$$N(\gamma) = \sum_b \mathbb{1}_{\{l_b(\gamma) > 1\}}.$$

A Existence of Lyapunov exponents

1.1 Attractive case

In the attractive case both \mathbb{D}_λ and \mathbb{H}_λ are super-multiplicative,

$$\mathbb{D}_\lambda(x + y) \geq \mathbb{D}_\lambda(x)\mathbb{D}_\lambda(y) \quad \text{and} \quad \mathbb{H}_\lambda(x + y) \geq \mathbb{H}_\lambda(x)\mathbb{H}_\lambda(y).$$

Hence both limits in (1.6) exist.

Furthermore, since the potential Φ is monotone in γ , $0 \leq \Phi(\gamma) \leq \Phi(\gamma \cup \eta)$,

$$\mathbb{D}_\lambda(x) \leq \mathbb{H}_\lambda(x) \cdot \sum_{\eta: 0 \rightarrow 0} e^{-\lambda|\eta|}. \quad (\text{A.1})$$

The relation (1.3) immediately implies that the right-most term in (A.1) is convergent for every $\lambda > \lambda_0$, and, consequently, that both limits in (1.6) are equal.

In order to check (1.3) note first of all that since Φ is non-negative, the partition function Z_n is bounded above by the total number of all n -step nearest neighbour trajectories; $Z_n \leq (2d)^n$. For the reverse direction, proceeding as in (Flury, 2007b), let us fix a number R and note that in view of the monotonicity of ϕ ,

$$Z_n \geq \frac{Z_n(\gamma \subset B_R)}{(2d)^n} e^{n \log(2d) - |B_R \cap \mathbb{Z}^d| \phi(n)} = \mathbb{P}_{\text{SRW}}(\gamma \subset B_R) e^{n \log(2d) - |B_R \cap \mathbb{Z}^d| \phi(n)},$$

where \mathbb{P}_{SRW} is the distribution of simple random walk on \mathbb{Z}^d . Since (Hryniv and Velenik, 2004)

$$\mathbb{P}_{\text{SRW}}(\gamma \subset B_R) \geq \exp\left\{-c(d) \frac{n}{R^2}\right\},$$

we conclude that for all R and n ,

$$\frac{1}{n} \log Z_n \geq \log(2d) - \frac{c(d)}{R^2} - |B_R \cap \mathbb{Z}^d| \frac{\phi(n)}{n}.$$

Thus, (1.3) indeed follows from (SL).

Inequality (1.7) is a trivial consequence of convexity and lattice symmetries. It remains to check that in the attractive case ξ_{λ_0} is strictly positive. However, again as in (Flury, 2007b),

$$\mathbb{H}_\lambda(x) = \sum_{n=\|x\|_1}^{\infty} \mathbb{E}_{\text{SRW}} e^{-\Phi(\gamma) - (\lambda - \lambda_0)n} \mathbb{1}_{\tau_x = n},$$

where τ_x is the first hitting time of x . As a result, $\xi_\lambda(x) \geq \phi(1)\|x\|_1$ for all $\lambda \geq \lambda_0$. \square

1.2 Repulsive case

First of all,

$$\mathbb{D}_\lambda(x) \leq \mathbb{H}_\lambda(x) \mathbb{D}_\lambda(0).$$

Thus, in view of (1.5), for every $\lambda > \lambda_0$ both exponents in (1.6) are automatically equal once it is proved that at least one of them is defined. We shall show that the first limit in (1.6) exists, using a familiar bubble diagram method: Consider

$$\mathbb{H}_\lambda(x) \mathbb{H}_\lambda(y) = \sum_{\gamma \in \mathcal{H}_x} \sum_{\eta \in x + \mathcal{H}_y} e^{-\Phi(\gamma) - \Phi(\eta)}.$$

Given a couple of trajectories $\gamma \in \mathcal{H}_x$ and $\eta \in x + \mathcal{H}_y$ define,

$$\underline{n} = \min \{l : \gamma(l) \in \eta\} \quad \text{and} \quad \bar{n} = \max \{k : \eta(k) = \gamma(\underline{n})\}.$$

The concatenated path

$$\tilde{\gamma} \triangleq (\gamma(0), \dots, \gamma(\underline{n}), \eta(\bar{n} + 1), \dots, \eta(|\eta|)) \triangleq \gamma_1 \cup \eta_1 \in \mathcal{H}_{x+y}.$$

Define also

$$\gamma_2 = (\gamma(\underline{n}), \dots, \gamma(|\gamma|)) \quad \text{and} \quad \eta_2 = (\eta(0), \dots, \eta(\bar{n})).$$

Evidently, one can recover γ and η from $\tilde{\gamma}$, γ_2 and η_2 up to, perhaps, an interchange of γ_2 and η_2 . Now, since γ_1 and η_1 intersect only at the end-point,

$$\begin{aligned}\Phi(\gamma) + \Phi(\eta) &\geq \Phi(\gamma_1) + \Phi(\gamma_2) + \Phi(\eta_1) + \Phi(\eta_2) \\ &= \Phi(\tilde{\gamma}) - \phi(1) + \Phi(\gamma_2) + \Phi(\eta_2).\end{aligned}$$

As a result,

$$\mathbb{H}_\lambda(x)\mathbb{H}_\lambda(y) \leq 2e^{\phi(1)} \left(\sum_z \mathbb{D}_\lambda(z)^2 \right) \mathbb{H}_\lambda(x+y). \quad (\text{A.2})$$

But $\sum_z \mathbb{D}_\lambda(z)^2 < \infty$ for every $\lambda > \lambda_0$, and the first limit in (1.6) is indeed well defined.

It remains to show that in the repulsive case $\xi_{\lambda_0} \equiv 0$. If this is not the case, then, as can be easily deduced from (A.2), there exists some finite constant c such that

$$\mathbb{D}_\lambda(x) \leq ce^{-\xi_\lambda(x)} \leq ce^{-\xi_{\lambda_0}(x)},$$

uniformly in $\lambda > \lambda_0$ and $x \in \mathbb{Z}^d$. By Fatou this would mean that $\sum_x \mathbb{D}_{\lambda_0}(x)$ converges. However, since we are in the repulsive case, $Z_n \geq e^{\lambda_0 n}$, and consequently,

$$\sum_x \mathbb{D}_{\lambda_0}(x) = \sum_n Z_n e^{-\lambda_0 n} = \infty.$$
