Summary. Transmission conditions based on Dirichlet-to-Neumann operators are known to yield optimal Schwarz methods that converge in a finite number of iterations when the subdomain decomposition has tree-like connectivity. However, it remains an open problem whether it is possible to construct a finitely terminating algorithm for arbitrary decompositions. In this article, we construct a Schwarz method in the discrete case that converges in two steps for any decomposition with sufficient overlap. In this method, every subdomain must communicate with all other subdomains, but only data along subdomain boundaries need to be exchanged.

1 Optimal Interface Conditions

The convergence rate of Schwarz-type domain decomposition methods is very sensitive to the transmission condition used. Thus, it is natural to ask, for a given PDE and a given decomposition into subdomains, whether we can find interface conditions that leads to convergence in a finite number of steps. For a decomposition into vertical strips, we know that Dirichlet-to-Neumann (DtN) operators yield such an optimal algorithm, see Nataf et al. [1994], Nataf and Rogier [1995], Magoulès et al. [2004]. A similar result for decompositions whose connectivity graph has no cycles is shown in Nier [1999]. It remains an open question to show whether similar operators exist for arbitrary decompositions.

The goal of this paper is to show that such an operator exists, at least at the discrete level, if we allow global communication between the subdomains, i.e., if each subdomain has access to the interface values of all the other subdomains. More precisely, we will show in section 3 how to construct a subdomain iteration that converges to the exact solution in at most two iterations. We will then show in section 4 that the only data that need to be exchanged between the subdomains are values along subdomain boundaries.

We note that in general, these optimal interface conditions involve nonlocal pseudo-differential operators, which are difficult to use in practice. Thus, the algorithm presented here is not meant to be implemented in a practical solver.

However, practical algorithms can be derived by approximating the optimal operators by differential operators, see Nataf and Rogier [1995], Gander et al. [2002] as well as Gander [2006] and references therein. Thus, our results serve as a starting point for this approximation process.

2 Notation and Assumptions

Let $\Omega \subset \mathbb{R}^n$ be a bounded open set. Suppose we want to solve the elliptic PDE

$$\mathcal{L}u = f \quad \text{on } \Omega, \quad u = g \quad \text{on } \partial\Omega \quad (1)$$

by discretizing it to obtain the non-singular system $A\mathbf{u} = \mathbf{f}$ and using a domain decomposition method. Let Σ be the degrees of freedom therein. Suppose Ω is subdivided into nonoverlapping subdomains $\tilde{\Omega}_j$, $j = 1, \dots, N$, and let $\tilde{\Sigma}_j$ be the discrete degrees of freedom contained within $\tilde{\Omega}_j$. Let $\{\Omega_j\}_{j=1}^N$ be an *overlapping* decomposition with degrees of freedom Σ_j , such that $\tilde{\Omega}_j \subset \Omega_j$ (and correspondingly $\tilde{\Sigma}_j \subset \Sigma_j$), and let R_j and R_{-j} be operators that restrict Σ onto Σ_j and $\Sigma \setminus \Sigma_j$ respectively. We then define, for each $l = 1, \dots, N$, the operator \tilde{R}_l , which has the same size as R_l , such that

$$[\tilde{R}_l]_{ij} = \begin{cases} 1 & \text{if } [R_l]_{ij} = 1 \text{ and } j \in \tilde{\Sigma}_l, \\ 0 & \text{otherwise.} \end{cases}$$

For each $j = 1, \dots, N$, we define the matrices

$$A_j = R_j A R_j^T, \quad B_j = R_j A R_{-j}^T, \quad C_j = R_{-j} A R_j^T, \quad D_j = R_{-j} A R_{-j}^T.$$

We assume that D_j is nonsingular for all j , so that the Schur complement $A_j - B_j D_j^{-1} C_j$ is well-defined and non-singular. We now state the main assumption that will be used throughout the paper.

Assumption 1 (Sufficient Overlap). For all $j = 1, \dots, N$, we have

$$\tilde{R}_j^T (R_j A - A_j R_j) = 0. \quad (2)$$

Assumption 1 states that the overlapping subdomain Σ_j needs to be sufficiently large, so that if v is a degree of freedom in $\tilde{\Sigma}_j$, then its stencil does not extend beyond Σ_j . This assumption is easily satisfied if the PDE is discretized using a compact stencil, because we can always construct Σ_j (and hence Ω_j) based on $\tilde{\Sigma}_j$ by extending it to include all points touched by the stencil.

3 Construction of the Method

The first step in constructing the method is to observe that we can obtain the exact subdomain solution $\mathbf{u}_j = R_j \mathbf{u}$ by solving the *Schur complement system*

$$(A_j - B_j D_j^{-1} C_j) \mathbf{u}_j = R_j \mathbf{f} - B_j D_j^{-1} R_{-j} \mathbf{f}. \quad (3)$$

If each subdomain has access to the right-hand side of all the other subdomains, then in principle we would be able to obtain \mathbf{u}_j in one pass by solving each Schur complement system independently. However, this would not lead to an optimal Schwarz method, because Schwarz methods only exchange information on \mathbf{u}_i along subdomain boundaries. Thus, to construct an optimal Schwarz method, we must try to recover $R_{-j} \mathbf{f}$ using subdomain solutions only. To do so, let us replace the unknown $R_{-j} \mathbf{f}$ in (3) by an arbitrary vector \mathbf{g} :

$$(A_j - B_j D_j^{-1} C_j) \tilde{\mathbf{u}}_j = R_j \mathbf{f} - B_j D_j^{-1} \mathbf{g}. \quad (4)$$

Note that $\tilde{\mathbf{u}}_j$ will no longer be the exact subdomain solution unless $\mathbf{g} = R_{-j} \mathbf{f}$. Nonetheless, we can substitute the definitions of A_j , B_j into (4) to get

$$R_j A (R_j^T - R_{-j}^T D_j^{-1} C_j) \tilde{\mathbf{u}}_j = R_j \mathbf{f} - R_j A R_{-j} D_j^{-1} \mathbf{g}. \quad (5)$$

If we multiply (5) from the left by \tilde{R}_j^T , then the sufficient overlap assumption (2) implies that $\tilde{R}_j^T R_j A = \tilde{R}_j^T A_j R_j$. Thus, we get

$$\tilde{R}_j^T A_j R_j (R_j^T - R_{-j}^T D_j^{-1} C_j) \tilde{\mathbf{u}}_j = \tilde{R}_j^T R_j \mathbf{f} - \tilde{R}_j^T A_j R_j R_{-j}^T D_j^{-1} \mathbf{g}.$$

Since $R_j R_j^T = I$ and $R_j R_{-j}^T = 0$ (they restrict to Σ_j and $\Sigma \setminus \Sigma_j$ respectively, which are disjoint sets), the above equation simplifies to

$$\tilde{R}_j^T A_j \tilde{\mathbf{u}}_j = \tilde{R}_j^T R_j \mathbf{f}. \quad (6)$$

This means if $\tilde{\mathbf{u}}_j$ solves (4) for some \mathbf{g} , then it is always possible to recover $\tilde{R}_j \mathbf{f}$, the *nonoverlapping* portion of \mathbf{f} , using $\tilde{\mathbf{u}}_j$ only; moreover, the result is *independent of \mathbf{g}* . Since $\mathbf{f} = \sum_{i=1}^N \tilde{R}_i^T R_i \mathbf{f}$ and $R_{-j} \tilde{R}_j^T = 0$, we can substitute these relations into (3) to obtain the following algorithm.

Algorithm 1. For $k = 1, 2, \dots$, and for $j = 1, \dots, N$, solve

$$(A_j - B_j D_j^{-1} C_j) \mathbf{u}_j^{k+1} = R_j \mathbf{f} - \sum_{i \neq j} T_{ji} \mathbf{u}_i^k, \quad (7)$$

where $T_{ji} = B_j D_j^{-1} R_{-j} \tilde{R}_i^T A_i$ is the transmission operator from Σ_i to Σ_j .

Theorem 1. *Let \mathbf{u} be the exact solution to the problem $A\mathbf{u} = \mathbf{f}$. Then for any initial guess \mathbf{u}_j^0 , Algorithm 1 converges to the exact solution in at most two iterations, i.e., $\mathbf{u}_j^2 = R_j \mathbf{u}$.*

Proof. Since \mathbf{u}_j^1 is the solution of (4) with $\mathbf{g} = \sum_{i \neq j} R_{-j} \tilde{R}_i^T A_i \mathbf{u}_i^0$, by (6) we have $\tilde{R}_j^T A_j \mathbf{u}_j^1 = \tilde{R}_j^T R_j \mathbf{f}$. So the second step of Algorithm 1 gives

$$\begin{aligned} (A_j - B_j D_j^{-1} C_j) \mathbf{u}_j^2 &= R_j \mathbf{f} - \sum_{i \neq j} B_j D_j^{-1} R_{-j} \tilde{R}_i^T A_i \mathbf{u}_i^1 \\ &= R_j \mathbf{f} - B_j D_j^{-1} R_{-j} \sum_{i \neq j} \tilde{R}_i^T R_i \mathbf{f} \\ &= R_j \mathbf{f} - B_j D_j^{-1} R_{-j} \sum_{i=1}^N \tilde{R}_i^T R_i \mathbf{f} \quad (\text{since } R_{-j} \tilde{R}_j^T = 0) \\ &= R_j \mathbf{f} - B_j D_j^{-1} R_{-j} \mathbf{f}, \end{aligned}$$

which is exactly the Schur complement formulation of the system with the correct right hand side. This implies $\mathbf{u}_j^2 = R_j \mathbf{u}$, as required. \square

We now compare Algorithm 1 with the well-known parallel Schwarz method with optimal transmission conditions for the *tree case*:

$$(A_j - B_j D_j^{-1} C_j) \mathbf{u}_j^{k+1} = R_j \mathbf{f} - \sum_{(i,j) \in E} (B_j R_{-j} R_i^T + B_j D_j^{-1} C_j R_j R_i^T) \mathbf{u}_i^k,$$

where the sum is over all Ω_i that are neighbors of Ω_j . We know that the classical optimal algorithm only converges after $D + 1$ iterations, where D is the diameter of the connectivity graph, see Nataf et al. [1994], Nier [1999], Magoulès et al. [2004]. In contrast, Theorem 1 shows that Algorithm 1 will converge in at most two iterations, regardless of the number of subdomains and the topology of the decomposition. This comes at a cost: Algorithm 1 requires global communication among subdomains at every iteration, unlike its classical counterpart, which only requires communication between neighbors. Finally, we will show numerically in Section 5 that the classical algorithm can fail to converge when the decomposition is not a tree, while Algorithm 1 converges for decompositions with arbitrary connectivity.

4 Sparsity Pattern

Formula (7) seems to suggest at every step of Algorithm 1, every subdomain must have access to the entire solution in every other subdomain. This is in fact not the case. To understand which values really need to be transmitted, we study the sparsity pattern of T_{ji} , the operator through which subdomain j obtains information from \mathbf{u}_i . We show that this operator contains mostly zero columns, which means the corresponding nodal values are in fact discarded (and thus not needed). We first introduce the notion of the support of a vector.

Definition 1 (Support of a vector). Let \mathbf{v} be a vector with degrees of freedom in Σ . Then the *support* of \mathbf{v} , denoted by $\text{supp}(\mathbf{v})$, is the set of all points in Σ corresponding to nonzero entries in \mathbf{v} .

The following equivalences are immediate based on the definitions of supp :

- (i) $\text{supp}(\mathbf{v}) \subset \Sigma_j \iff R_j^T R_j \mathbf{v} = \mathbf{v} \iff R_{-j} \mathbf{v} = 0$,
- (ii) $\text{supp}(\mathbf{v}) \subset \tilde{\Sigma}_j \iff \tilde{R}_j^T R_j \mathbf{v} = \mathbf{v}$,
- (iii) $\text{supp}(\mathbf{v}) \cap \Sigma_j = \emptyset \iff R_{-j}^T R_{-j} \mathbf{v} = \mathbf{v} \iff R_j \mathbf{v} = 0$.
- (iv) $\text{supp}(\mathbf{v}) \cap \tilde{\Sigma}_j = \emptyset \iff \tilde{R}_j \mathbf{v} = 0$.

Next, we identify the zero columns of T_{ji} . We do so by multiplying T_{ji} by a standard basis vector \mathbf{e}_x and checking whether the product is zero.

Lemma 1. *Let $x \in \Sigma_i$ and \mathbf{e}_x be its basis vector (1 at x and 0 everywhere else). Then we have $T_{ji} R_i \mathbf{e}_x = 0$ in each of the following cases:*

- (i) $\text{supp}(\mathbf{Ae}_x) \cap \tilde{\Sigma}_i = \emptyset$;
- (ii) $\text{supp}(\mathbf{Ae}_x) \subset \Sigma_j$;
- (iii) $\{x\} \cup \text{supp}(\mathbf{Ae}_x) \subset \tilde{\Sigma}_i \setminus \Sigma_j$.

Proof. First, we rewrite $T_{ji}R_i\mathbf{e}_x$ as

$$T_{ji}R_i\mathbf{e}_x = B_j D_j^{-1} R_{-j} \tilde{R}_i^T A_i R_i \mathbf{e}_x = B_j D_j^{-1} R_{-j} \tilde{R}_i^T R_i \mathbf{Ae}_x$$

by the sufficient overlap condition. We then consider the three cases:

- (i) $\text{supp}(\mathbf{Ae}_x) \cap \tilde{\Sigma}_i = \emptyset$: we have

$$T_{ji}R_i\mathbf{e}_x = B_j D_j^{-1} R_{-j} (\tilde{R}_i^T R_i \mathbf{Ae}_x) = B_j D_j^{-1} R_{-j} \underbrace{(R_i^T \tilde{R}_i \mathbf{Ae}_x)}_{=0} = 0.$$

- (ii) $\text{supp}(\mathbf{Ae}_x) \subset \Sigma_j$:

We have $\text{supp}(\tilde{R}_i R_i^T \mathbf{Ae}_x) \subset \text{supp}(\mathbf{Ae}_x) \subset \Sigma_j$, so $R_{-j} \tilde{R}_i R_i^T \mathbf{Ae}_x = 0$.

- (iii) $\{x\} \cup \text{supp}(\mathbf{Ae}_x) \subset \tilde{\Sigma}_i \setminus \Sigma_j$:

Since $\text{supp}(\mathbf{Ae}_x) \subset \tilde{\Sigma}_i$, we have $\tilde{R}_i R_i^T \mathbf{Ae}_x = \mathbf{Ae}_x$. Now consider the linear system $D_j \mathbf{y} = R_{-j} \mathbf{Ae}_x$, which can be rewritten as $R_{-j} A R_{-j}^T \mathbf{y} = R_{-j} \mathbf{Ae}_x$. Since $x \notin \Sigma_j$, we see that $\mathbf{y} = R_{-j} \mathbf{e}_x$ satisfies the equation (because $R_{-j}^T R_{-j} \mathbf{e}_x = \mathbf{e}_x$). This is also the unique solution because D_j is assumed to be non-singular. Thus, we have $D_j^{-1} R_{-j} \tilde{R}_i^T R_i \mathbf{Ae}_x = D_j^{-1} R_{-j} \mathbf{Ae}_x = R_{-j} \mathbf{e}_x$. Now we multiply from the left by B_j to obtain

$$T_{ji}R_i\mathbf{e}_x = \underbrace{R_j A R_{-j}^T}_{B_j} R_{-j} \mathbf{e}_x = R_j \mathbf{Ae}_x = 0,$$

since $\text{supp}(\mathbf{Ae}_x)$ lies completely outside Σ_j . \square

Each of the three cases in Lemma 1 is illustrated in Figure 1, where the hollow stencils indicate points that get mapped to zero by T_{ji} . Case (i) (top right-hand corner) happens when the stencil falls completely outside $\tilde{\Omega}_i$; case (ii) (bottom-left of Ω_i) occurs when the stencil falls entirely within Ω_j . Finally, case (iii) occurs when the stencil is completely inside $\tilde{\Omega}_i \setminus \Omega_j$, just like the stencil near the center of the graphic. Thus, we see from Figure 1 that the only points with $T_{ji}R_i\mathbf{e}_x \neq 0$ are those indicated by solid nodes, i.e. those that are so close to the boundary of $\tilde{\Omega}_i \setminus \Omega_j$ that their stencils straddle the boundary. These, in fact, are the only nodal values that must be transmitted. For a five-point stencil, this corresponds to a layer with a thickness of two nodes (one on each side of the boundary, see Figure 2 in the next section); for wider stencils, e.g., for higher-order equations, this layer becomes thicker, but the number of values transmitted is still proportional to the length of $\partial(\tilde{\Omega}_i \setminus \Omega_j)$, which is one dimension lower than the set of all nodes in $\tilde{\Omega}_i$. If we define P_{ji} to be the restriction operator from Σ_i to the set of ‘‘boundary nodes’’ (i.e., nodes whose stencils straddle $\partial(\tilde{\Omega}_i \setminus \Omega_j)$), then we can rewrite Algorithm 1 as follows:

Fig. 1. A sketch showing stencils associated with different points in Ω_i . Stencils with solid nodes indicate points x at which $T_{ji}R_i\mathbf{e}_x \neq 0$; those with hollow nodes indicate points at which $T_{ji}R_i\mathbf{e}_x = 0$ for the three cases indicated in Lemma 1.

Algorithm 2. For $k = 1, 2, \dots$, and for $j = 1, \dots, N$, solve

$$(A_j - B_j D_j^{-1} C_j) \mathbf{u}_j^{k+1} = R_j \mathbf{f} - \sum_{i \neq j} \tilde{T}_{ji} \tilde{\mathbf{u}}_i^k,$$

where $\tilde{T}_{ji} = B_j D_j^{-1} R_{-j} \tilde{R}_i^T A_i P_{ji}^T$ and $\tilde{\mathbf{u}}_i^k = P_{ji} \mathbf{u}_i^k$.

Remark. Algorithms 1 and 2 have identical iterates if the same initial guesses are used. Their only difference is that the latter does not transmit data corresponding to zero columns in T_{ji} , i.e., data that would be discarded anyway. This reduces the communication costs by a factor of H/h , where h is the fine mesh parameter and H is the size of the subdomain.

5 Numerical Examples

In this section, we present two examples in which we compare the convergence behavior of Algorithm 2 with that of the classical parallel Schwarz method with optimal transmission conditions, which is known to converge in a finite number of iterations in the tree case. For simplicity, in both cases we solve the $A\mathbf{u} = \mathbf{f}$, where A is the matrix obtained from the standard 5-point discretization of the 2D Poisson equation with Dirichlet boundary conditions, and \mathbf{f} is a random vector. However, since the methods are derived purely algebraically, they are in principle applicable to any discretized PDE, provided that we can define the subdomains so that they satisfy the sufficient overlap assumption, and that the subdomain problems are well posed.

Example 1. Here we decompose a rectangular domain into 6 vertical strips, as shown in Figure 2(a). Since the diameter of the connectivity graph is $D = 5$, we know that the parallel Schwarz method with optimal transmission conditions will converge in at most 6 steps; the numerical results in Table 1

confirms this. In contrast, Algorithm 2 converges in exactly two steps; this is in agreement with Theorem 1. Finally, Figure 2(a) shows the communication pattern for both algorithms: the top half shows which values are needed by Ω_j in Algorithm 2, whereas the bottom half shows those needed in the classical algorithm. As predicted by Lemma 1, the only nodal values that need to be transmitted are located on either side of the subdomain boundaries. Also, whereas the classical algorithm only takes information from its neighbors, Algorithm 2 communicates with every subdomain, which makes it possible to converge in two iterations.

Example 2. In this example, we use the 4×4 decomposition shown in Figure 2(b). Since the connectivity graph is not a tree, we can no longer expect optimal parallel Schwarz to converge after a finite number of steps. Indeed, we see from Table 1 that the iteration diverges. This happens because of two reasons. First, since there are points belonging to more than two subdomains (i.e., cross points), optimal parallel Schwarz actually applies redundant updates at these points, leading to divergence, see Efstathiou and Gander [2003]. In addition, unlike the tree case, $\partial\Omega_j$ is divided among several subdomains; thus, it is no longer possible to interpret the boundary values obtained by Ω_j as the trace of a function u^{ext} in $\Omega \setminus \Omega_j$ whose error $u^{ext} - u|_{\Omega \setminus \Omega_j}$ is harmonic outside Ω_j . Instead, the error fails to be harmonic at the partition points. Despite these difficulties, Algorithm 2 still converges in two iterations; the operators \tilde{T}_{ji} are able to extract the right interface information and combine them the right way for the method to converge.

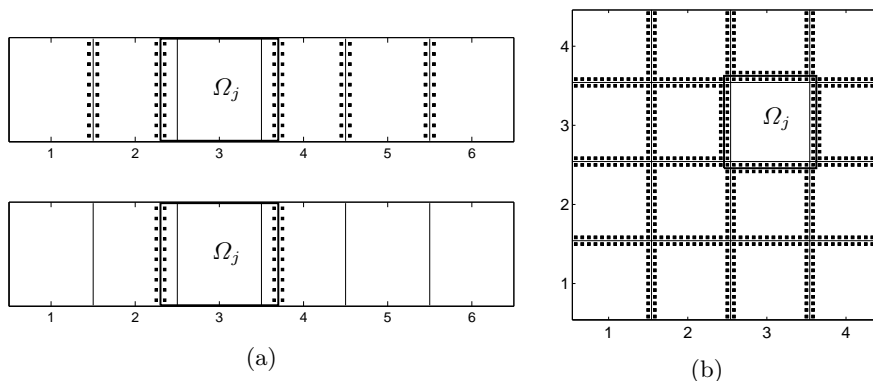

Fig. 2. Communication pattern for two decompositions into subdomains. Black squares indicate nodal values required by Ω_j , which is enclosed by thick solid lines. (a) decomposition into vertical strips. The top figure shows the values required by Algorithm 2, and the bottom those required by classical Parallel Schwarz with optimal transmission conditions. (b) a 4×4 decomposition, shown with the communication pattern for Algorithm 2.

Table 1. Parallel Schwarz with optimal transmission conditions versus Algorithm 2. In each case, we report the maximum L^∞ errors over all subdomains.

Its.	Example 1 (6×1)		Example 2 (4×4)	
	Parallel Schwarz	Algorithm 2	Parallel Schwarz	Algorithm 2
1	3.605×10^0	3.681×10^0	6.987×10^1	6.965×10^1
2	2.176×10^{-1}	1.066×10^{-14}	1.191×10^2	8.527×10^{-13}
3	1.252×10^{-2}		5.438×10^1	
4	7.328×10^{-4}		4.652×10^2	
5	3.278×10^{-5}		1.118×10^3	
6	1.066×10^{-14}		3.894×10^3	

6 Conclusion

We presented a new Schwarz method that converges in exactly two iterations when the domain decomposition satisfies the sufficient overlap assumption. Unlike the classical algorithm, the optimal transmission conditions we derived can handle arbitrary subdomain topologies. In our algorithm, each subdomain must communicate with all the other subdomains at each step; however, one only needs to exchange data along a coarse grid structure containing the subdomain boundaries. Since its derivation is based only on sparse matrices, the method is in principle applicable to any PDE, or even systems of PDEs, as long as the subdomain problems remain solvable. Ongoing work focuses on deriving approximate local operators to obtain more efficient implementations.
